Cancer is the second leading cause of death worldwide and cancer-related deaths are rising. A major challenge of oncology today is to find treatments that can target and destroy cancer cells while being tolerated by the patient. This goal can only be achieved when we gain a deeper understanding of the biology and physiology of tumor cells, including the mechanisms that lead to uncontrolled growth and the development of resistance to therapy. Currently, the main strategy to combat cancer is through the use of cytotoxic drugs, which are thought to directly kill cancer cells and/or their microenvironment. However, resistance to these drugs has become a major cause for treatment failure, underscoring the need for novel treatment strategies.

Cell death is an important tumor cell property and can have a profound effect on the microenvironment, including the immune system, and the tumor cell itself. Tumor cell death is not restricted to physical forms of cell death. Oncogenesis and cancer progression are driven by a myriad of molecular changes in tumor cells that lead to metabolic reprogramming and altered gene expression. By virtue of the immense variety of proteins, RNAs, lipids and metabolites produced by tumor cells, these cells can also function as signaling centers, controlling the tumor microenvironment and surrounding immune cells. This review will focus on the molecular mechanisms that enable tumor cells to produce and release exosomes containing proteins, RNAs, lipids and metabolites.
